Abstract. According to recent studies, internal mixing of black carbon (BC) with other aerosol materials in the atmosphere alters its aggregate shape, absorption of solar radiation, and radiative forcing. These mixing state effects are not yet fully understood. In this study, we characterize the morphology and mixing state of bare BC and BC internally mixed with sodium chloride (NaCl) using electron microscopy and examine the sensitivity of optical properties to BC mixing state and aggregate morphology using a discrete dipole approximation model (DDSCAT). DDSCAT is flexible in simulating the geometry and refractive index of particle aggregates. DDSCAT predicts a higher mass absorption coefficient (MAC), lower single scattering albedo (SSA), and higher absorption Angstrom exponent (AAE) for bare BC aggregates that are lacy rather than compact. Predicted values of SSA at 550 nm range between 0.16 and 0.27 for lacy and compact aggregates, respectively, in agreement with reported experimental values of 0.25 ± 0.05. The variation in absorption with wavelength does not adhere precisely to a power law relationship over the 200 to 1000 nm range. Consequently, AAE values depend on the wavelength region over which they are computed. The MAC of BC (averaged over the 200–1000 nm range) is amplified when internally mixed with NaCl (100–300 nm in radius) by factors ranging from 1.0 for lacy BC aggregates partially immersed in NaCl to 2.2 for compact BC aggregates fully immersed in NaCl.

The SSA of BC internally mixed with NaCl is higher than for bare BC and increases with the embedding in the NaCl. Internally mixed BC SSA values decrease in the 200–400 nm wavelength range, a feature also common to the optical properties of dust and organics. Linear polarization features are also predicted in DDSCAT and are dependent on particle size and morphology.

This study shows that DDSCAT predicts complex morphology and mixing state dependent aerosol optical properties that have been reported previously and are relevant to radiative transfer, climate modeling, and interpretation of remote sensing measurements.

1 Introduction

The most recent Intergovernmental Panel on Climate Change report (IPCC, 2007) established that the radiative forcing of all aerosol types should be estimated in order to understand their effects on the earth-atmosphere energy budget. The successful accomplishment of this goal requires an accurate parameterization of aerosol optical properties consistent with their physical and chemical properties. This study focuses on black carbon (BC), a product of combustion of fossil and biomass fuels, which is the strongest sunlight-absorbing aerosol species (Jacobson, 2001) and a critical component of...
the global and regional climate (Bond et al., 2004; Bond and Mikhaylov, 2005; Ramanathan and Carmichael, 2008).

When aerosols are transported far from their emission sources, their climatic and environmental impacts are delocalized from their source regions (Kanakidou et al., 2005; Pace et al., 2006; Smirnov et al., 2011). During atmospheric transport, BC becomes increasingly mixed with weak or non-absorbing materials, such as sulfates, nitrates, organics, dust, and sea salt (Li et al., 2003; Mikhaylov et al., 2006; Shiraiwa et al., 2007, 2010; Xue et al., 2009; Moffet and Prather, 2009; Bueno et al., 2011; Laskin et al., 2012). The absorbing and scattering efficiencies of BC particles, which are aggregates of primary spheres, i.e., monomers (Tian et al., 2006), depend on primary spherule size, aggregate compactness, and mixing state with other species. Aggregate compactness (fractal dimension) is affected by temperature changes, water, and other aerosol material.

For example, laboratory experiments show that BC aggregates become more compact when embedded in low-viscosity materials, such as glutaric and sulfuric acids (Xue et al., 2009; Zhang et al., 2008). Also, coating BC with non-absorbing compounds, including organic and inorganic acids, leads to an enhancement in light absorption and scattering (e.g., Zhang et al., 2008; Xue et al., 2009; Shiraiwa et al., 2010). Xue et al. (2009) found that (i) thin coatings of dicarboxylic acids on BC aggregates enhance light scattering significantly and light absorption slightly and (ii) humidity cycling of glutaric acid coated BC can irreversibly restructure BC aggregates and further modify SSA.

These studies indicate that it is necessary to account for the optical effects of changes to the mixing state and morphology of BC particles when modeling their interaction with sunlight. However, optical properties are not always reproduced by commonly used models, such as the Lorenz–Mie–Debye theory (Bohren and Huffman, 1983), the Rayleigh–Debye–Gans (RDG) approximation (Zhao and Ma, 2009) and the effective medium theory (Bruggeman, 1935; Maxwell Garnett, 1904). For example, there is a discrepancy between modeled and measured mass absorption coefficient (MAC) of bare BC aggregates (Bond and Bergstrom, 2006; Kahnert, 2010a,b). Bueno et al. (2011) found that the amplification in absorption observed when BC was coated with a surrogate of sulfuric acid was smaller than the predictions using core-shell Mie theory, and they suggested that the discrepancy was due to misrepresentation of the morphology of the coated particles and/or structure of the BC core in the model.

The optics of particles with complex shapes and refractive index distribution can only be calculated using computationally intensive techniques such as T-matrix and discrete dipole approximation (DDA). T-matrix is applicable to homogeneous particles (Mishchenko et al., 1996), while DDA is applicable to both homogeneous particles and particles with anisotropic composition (Purcell and Pennypacker, 1973; Drain and Flatau, 1994, 2010).

Recent studies show the optical effects of (i) treating bare BC as an aggregation of spherical primary particles rather than as a single sphere (e.g., Liu et al., 2008; Kahnert, 2010a,b; Kahnert and Devasthale, 2011; Wu et al., 2012) and (ii) BC aggregates embedded in other materials (e.g., Liu et al., 2012; Kahnert et al., 2012; Adachi et al., 2010; Liu et al., 2011; Worringen et al., 2008). The studies on bare BC make use of T-matrix, while those on coated BC aggregates make use of core-mantle theory involving two effective medium theories (Liu et al., 2012); finite difference time domain (Wu et al., 2012) in the IR region and DDA (Adachi et al., 2010; Kahnert et al., 2012). Liu et al. (2008) showed that the relationship between the absorption cross section and the compactness of the BC aggregate is a complex function of the refractive index, the number of monomers, and the monomer size. Further, they found that T-matrix computed optical properties of bare BC aggregates differ profoundly from those calculated for the respective volume-equivalent BC spheres and for the respective external mixtures of BC monomers under the assumption that there are no electromagnetic interactions between the monomers. Kahnert and Devasthale (2011) found that the radiative forcing at the top of the atmosphere is two times higher if fresh BC is modeled as an aggregate instead of a homogeneous sphere. Radiative forcing due to aggregates with open chainlike (lacy) structures is 1.1–1.6 times higher than for aggregates with a more compact shape. Adachi et al. (2010) showed that many BC particles from a mega-city have lacy shapes even after being surrounded by organic matter and that BC is located in off-center positions within its host material. Off-center embedded BC aggregates absorb sunlight less efficiently than if compact and located near the center of its host particle (Fuller et al., 1999). Further, Adachi et al. (2010) found that radiative forcing is 20% less when modeling internally mixed BC particles as embedded lacy aggregates than as a simple core-shell shape, which is the shape assumed in many climate models.

The impact of shape on aerosol optical properties is a relevant topic as well for interpretation of remote sensing measurements. Any retrieval approach used in analyses of radiometric and polarimetric data requires a model of aerosol particle shape, and in the majority of studies the model of spherical or randomly oriented spheroids particles has been adopted (e.g., Deuze et al., 2001; Hasekamp et al., 2011; Dubovik et al., 2010). Mishchenko and Travis (1997a,b) related the possibility of improvement of satellite aerosol retrievals with use of spectral multi-angular polarization as well as intensity of reflected sunlight. The amount of light escaping the top of the atmosphere is affected by the angle at which the light is reflected by the surface or atmosphere. The MISR sensor on the Terra satellite uses this dependency to separate the aerosol signal from that of surface reflectance and determines the aerosol properties (Kaufman et al., 2002). Polarization of the scattered sunlight is extremely sensitive to such properties of aerosols as particle...
size relative to the wavelength and refractive index, which often makes possible the retrieval of these parameters from polarimetric observations (Dlugach and Mishchenko, 2005, 2008). It is known that linear polarization is strongly dependent on particle shape (e.g., Mishchenko et al., 1996, 2002; Wu et al., 2012). It should therefore be expected that particle non-sphericity can affect the retrieval of aerosol microphysical characteristics, such as refractive index and size, from remote-sensing data.

This paper describes a sensitivity study on the effects of aggregation and internal mixing on optical properties of BC, including absorption, scattering, AAE, linear polarization, scattering phase function, and others. We applied a DDA model to examine these effects for black carbon particles – bare and mixed with salt – that we characterized with scanning and transmission electron microscopes. The discrete dipole approximation model presented captures complexities in particle morphology that other models do not and thus may be useful in predicting aerosol optical properties in climate modeling and interpreting data remotely measured with satellites.

2 Methods

2.1 Particle generation and morphological characterization

We generated bare BC and BC internally mixed with NaCl. We chose NaCl because (i) NaCl is an atmospherically abundant inorganic compound derived from evaporated ocean water and (ii) chemical aging and atmospheric processing of sea salt particles may take place in many geographic areas where marine aerosol interacts with anthropogenic pollutants, such as BC, sulfate, and organic aerosol (Laskin et al., 2012; Li et al., 2003; Smirnov et al., 2011; Pace et al., 2006). Bare BC was generated by nebulizing and drying a stable suspension of BC in pure water. The BC was made with a non-premixed methane-air flame (Kirchstetter and Novakov, 2007). The BC from this flame has a morphology and MAC (8.5 m$^2$g$^{-1}$ at 550 nm) consistent with freshly generated soot particles (Moosmuller et al., 2009; Bond and Bergstrom, 2006). Aqueous suspensions of the flame BC were prepared after its collection on Teflon filters and exposure to ozone, which transformed the BC from a hydrophobic to a hydrophilic state (Chughtai, 1991), and after which the BC readily mixed with water. To generate coated BC, we dissolved NaCl in the BC suspension and co-nebulized both species together.

The mixing state and morphology of the aerosol mixture were determined using scanning and transmission electron microscopy (SEM and TEM). SEM and TEM images provided morphological information, including aggregate shape, number and size of monomers, and state of mixing with NaCl. We used these images to model aggregates with the same characteristics in the DDA model.

2.2 Morphological characterization of aggregates

BC particles can be characterized as a mass fractal, where each particle is represented as an aggregate of the same sized primary spherical particles (monomers), with the following formula

$$N_m = k_0(R_g^{3D}/r_m)^{D_k},$$

where $N_m$ is the number of monomers, $k_0$ is the prefactor (structural coefficient), $R_g^{3D}$ is the three dimensional radius of gyration, $r_m$ is the monomer radius, and $D_k$ is the mass fractal dimension. Techniques involving transmission/scanning electron microscopy coupled with digital image analysis have found use in determining $D_k$ of aggregates from their projected images. Several studies have suggested that $R_g^{3D}$ can be extracted by measuring the projected parameter $L_{max}$ (Brasil et al. 1999) suggested a ratio of $L_{max}^{2D}/R_g^{3D} = 3.0 \pm 0.1$, for all $N_m$ and overlap factors. $D_k$ can be extracted from an empirical statistical scaling power law that relates the size of the aggregate to the ratio $L_{max}^{2D}/r_m$:

$$\log(N_{proj}) = \log(k_0) + D_k \log(R_g^{3D}/r_m)$$

$$= \log(k_0) + D_k \log(L_{max}^{2D}/3r_m),$$

where the projected number of monomers ($N_{proj}$) in Eq. (2) is determined from the ratio of the aggregate projected area $A_{agg}$ to the average monomer area $A_p$. An empirical formula relating $N_m$ and $N_{proj}$ is proposed by Chakrabarty et al. (2011), where $N_m$ can be corrected for an overlapping factor:

$$N_m/N_{proj} = 0.46e^{0.68D_k}.$$
material and $k = 2\pi/\lambda$. In DDSCAT, the target effective radius, $a_{\text{eff}}$, is defined as the radius of a sphere with the same volume as the target

$$a_{\text{eff}} = (3V/4\pi)^{1/3}$$

(5)

$$V = Na^3,$$

(6)

where $N$ is the number of dipoles and $V$ is the volume.

The DDSCAT output variables of interest for this study are

1. the dimensionless quantity $\alpha_i$ with $i = (1, 2, 3)$:

$$\alpha_i = I_i/0.4Ma_{\text{eff}}^2$$

(7)

$$M = \rho V,$$

(8)

where $I_i$ is the moment of inertia tensor, $\rho$ is the density, and $V$ is the volume of the modeled aggregate. For a solid sphere, e.g., the case S in our study, $\alpha_i = 1$ with $i = (1, 2, 3)$.

2. The absorption, scattering and extinction efficiencies ($Q_{\text{abs,scat,ext}}(\lambda)$) defined as

$$Q_{\text{abs,scat,ext}} = C_{\text{abs,scat,ext}}/\pi a_{\text{eff}}^2,$$

(9)

where $C_{\text{abs,scat,ext}}(\lambda)$ are the absorption, scattering and extinction optical cross-sections.

3. The $4 \times 4$ Mueller scattering intensity matrix ($S_{ij}$) with $i, j = (1, 2, 3, 4)$ describing the complete scattering properties of the target for specified scattering directions.

From these variables we calculated:

1. the porosity ($P$) of the structure of modeled aggregates as defined by Shen et al. (2008):

$$P = 1 - f$$

(10)

$$f = [(\alpha_2 + \alpha_3 - \alpha_1)(\alpha_3 + \alpha_1 - \alpha_2)(\alpha_1 + \alpha_2 - \alpha_3)]^{-1/2},$$

(11)

where $\alpha_i$ is defined in Eq. (7). The value of $P$ is larger for a lacy aggregate than it is for a compact aggregate. $P$ is introduced because the commonly used $D_l$ is not a good measure of porosity and compactness.

2. The mass absorption coefficient (MAC):

$$\text{MAC} = C_{\text{abs}}/\text{mass}_{\text{BC}}$$

(12)

$$\text{mass}_{\text{BC}} = \rho \frac{4}{3} \pi a_{\text{eff}}^3,$$

(13)

where $\rho$ is the density of BC and $a_{\text{eff}}$ is the effective radius.

3. The aerosol absorption Angstrom exponent (AAE) computed from the slope of the linear fit passing though MAC curves (in log-log scale):

$$\text{AAE} = \frac{-\triangle \log \text{MAC}}{\triangle \log (\lambda)},$$

(14)

where AAE = 1 if MAC $\propto \lambda$, and AAE = 0 if MAC is constant with wavelength. AAE is presented for three wavelength regions.

4. The single scattering albedo (SSA):

$$\text{SSA} = Q_{\text{scat}}(\lambda)/Q_{\text{ext}}(\lambda).$$

(15)

5. The scattering phase function ($S_{11}(\theta)$) as the intensity ($F$) at $\theta$ relative to the normalized integral of the scattered intensity at all angles ($\int_0^\pi F(\theta) \sin(\theta) d\theta$). The scattering angle, $\theta \in [0, \pi]$, is defined as the angle between the incidence and scattering directions.

6. The degree of linear polarization $-S_{12}(\theta)/S_{11}(\theta)$.

To focus on the effects of aggregation and mixing on optical properties of BC, refractive indices of BC and NaCl were treated as constant in the spectral range between 200 and 1000 nm (Moffet and Prather, 2009), where $m_{\text{BC}} = 1.95 - 0.79i$ and $m_{\text{NaCl}} = 1.5$. We assume the density of BC $\rho_{\text{BC}} = 1.8\text{ g cm}^{-3}$ (Bond and Bergstrom, 2006). Reported optical properties are the average values computed for 1000 random target orientations (Kahnert et al., 2012) and 9 multiple scattering planes that satisfy the condition $|m|kd < 0.3$. Optical properties were also computed for 64 (according to Shen et al., 2008, 2009) and 3000 orientations.

As noted below, we found that 64 target orientations were sufficient to converge on the optical properties (i.e., MAC and SSA) of bare and internally mixed compact aggregates, but a larger number of orientations was required to attain converged orientation averaged values of the MAC of internally mixed lacy aggregates. Predicted optical properties using 1000 target orientations are consistent with results using 3000 orientations.

3 Results

3.1 Uncoated BC aggregates

The SEM images in Fig. 1 show the fractal nature of the generated bare BC. The aggregates are composed of spherical primary particles (monomers) of about the same size. The characteristics of the bare BC studied are presented in Table 1 and Fig. 2. The heterogeneity of the morphological characteristics are representative of the SEM images analyzed. Cases A through E correspond to five types of aggregates that vary in compactness (porosity), number and size.
of monomers. Case S is a homogeneous sphere approximation (HSA). Optical properties are compared for cases A and C, and cases D, E and S, which have the same number and size of monomers and/or effective radius but different porosities. Case B presents, instead, a smaller size and number of monomers.

Predicted values of MAC are shown in Fig. 3a for a composite of aggregates. At wavelengths smaller than 550 nm, MAC values depend on the morphology of the BC aggregate. The MAC curves separate in this wavelength range as a result of the dependency between the size of the particle and the incident radiation wavelength. For larger bare BC aggregates, the separation starts at longer wavelengths. (This is also evident in the case of larger coated BC aggregates, as shown in Fig. 7a).

Generally, MAC is higher for smaller aggregates (with lower mass). Higher MAC values are found for lacy aggregates compared to more compact structures (compare cases A vs. C and D vs. E). This general behavior was also found by Liu et al. (2008) and Kahnert and Devasthale (2011).

Compared to aggregates (cases D and E), the homogeneous sphere approximation (HSA, case S) exhibits significantly lower MAC below 550 nm and slightly higher MAC in the Rayleigh regime (550–1000 nm). In all cases, MAC lies between 6.3 and 7.0 m² g⁻¹ at 550 nm, in agreement with the range of values reported by Bohren and Huffman (1983); Martins et al. (1998); Fuller et al. (1999); Bergstrom (1973); Bond and Bergstrom (2006); Adachi et al. (2007).

For aggregates with a much larger number of monomers (600) than those modeled in this study, Kahnert (2010b) estimated MAC values (at 550 nm) of 5.2 ± 0.1 m² g⁻¹ for lacy aggregates, 4.9 ± 0.1 m² g⁻¹ for compact aggregates, and 3.3 ± 0.4 m² g⁻¹ for spheres. These lower values are likely the result of the large number of aggregate monomers (see Eq. 12) where compact aggregates have a low porosity.

The variation in absorption with wavelength does not adhere precisely to a power law relationship over the 200 to 1000 nm range. Consequently, computed AAE values depend on the wavelength range considered. As shown in Table 1, AAE values computed between 288 and 550 nm (0.73–0.92) are smaller than those computed between 550 and 1000 nm (0.86 to 1.04). AAE values of ~1 in the Rayleigh regime (550–1000 nm) are consistent with observations (e.g., Russell et al., 2010) and other theoretical results (Bohren and Huffman, 1983; Bergstrom, 1973).

![Fig. 1. Two SEM images of bare BC aggregates. In each image, two types of morphologies are evident: chain-like (lacy) structures and compact structures.](image-url)
Predicted values of AAE were sensitive to aggregate compactness and monomer size. Compact aggregates exhibited lower AAE values than lacy aggregates (compare cases A vs. C and cases D vs. E). Compact aggregates with the same monomer diameter (cases C and E), while having different aggregate size, have lower AAEs than the aggregate with smaller diameter monomers (case B). AAE values are also different for aggregates with the same porosity (cases B and E) but with different numbers of differently sized monomers.

Predicted values of SSA are shown in Fig. 3b. Values of SSA are higher for compact aggregates than for lacy aggregates (compare cases D vs. E and A vs. C), in agreement with Kahnert and Devasthale (2011). Compact aggregates are characterized by a higher scattering cross section than lacy aggregates, also found by Liu et al. (2008), due to a stronger scattering interaction and stronger electromagnetic coupling between spherules. The SSA values for BC aggregates and the homogeneous sphere (HSA) differ markedly (compare cases D, E and S). The 550 nm SSA for BC aggregates ranges between 0.16 and 0.27 as a function of compactness and size of the aggregate, in agreement with the suggested value of $0.25 \pm 0.05$ (Kahnert, 2010b; Fuller et al., 1999), while a much higher SSA of 0.39 is predicted for the HSA case.

It is noteworthy that, for the size of particles presented here, MAC values are sensitive to particle shape only at short wavelengths where incoming solar radiation is weak (due to absorption of the ozone layer). On the other hand, the scattering coefficients are sensitive to particle shape over the full solar spectrum. As a result, aerosol SSA, and thus aerosol radiative forcing, is sensitive to particle shape. Further, SSA is retrieved from remote sensing data, where retrieval algorithms approximate particles as having homogeneous
spherical or spheroidal shape (Dubovik et al., 2006; Mischenko et al., 2000). Given the sensitivity of computed values of SSA to BC shape approximation (sphere or aggregate of spheres) and aggregate porosity (shown in Fig. 3b), ambiguities in aerosol composition or mixtures retrieved may be expected.

### 3.2 BC internally mixed with NaCl

The TEM images in Fig. 4 illustrate different types of internal mixing: (a) total inclusion of BC in a NaCl particle, (b) partial inclusion and partial surface contact of BC on the NaCl surface, and (c) inclusion of NaCl in a larger BC aggregate. SEM images of aerosol samples from field campaigns, including the second Aerosol Characterization Experiment (Li et al., 2003) and the Carbonaceous Aerosol and Radiative Effects Study (Laskin et al., 2012), show sea salt aerosol with a smoothed cubic/rectangular prism shape, internal mixtures of NaCl with BC aggregates, and NaCl/BC mixtures with features similar to those observed in our samples, with a partial inclusion and partial surface contact of BC on the NaCl surface (Fig. 4b). As indicated in Table 2 and Figs. 5 and 6, we simulated these different possibilities: two cases of complete BC inclusion in NaCl (cases FI and GI) and two cases of BC inclusion and surface contact of BC on NaCl (case FIS and GIS). For comparison, we also modeled two cases (F and G) of lacy and compact BC aggregates in bare condition (i.e., not mixed with NaCl).

Predicted values of MAC are shown in Fig. 7a. Compared to bare BC aggregates, the MAC of BC mixed with NaCl can be substantially larger, depending on the extent of mixing and BC morphology. Absorption amplification factors computed as $MAC(\lambda)/MAC(\lambda)_{bare}$ at $\lambda = 550$ nm are listed in Table 2. We also computed absorption amplification factors averaged over the 200–1000 nm range, which were $1.0 \pm 0.0$ for lacy BC aggregates partially included in NaCl (case FIS), $1.7 \pm 0.1$ for lacy BC aggregates fully included in NaCl (case FI), $1.4 \pm 0.1$ for compact BC with an inclusion of NaCl (case GIS) and $2.2 \pm 0.2$ for compact BC aggregates fully immersed in NaCl (case GI).

The amplification factors stated above correspond to optical properties averaged over 1000 target orientations. Amplification factors computed using 3000 target orientations were the same. Amplification factors computed using 64 target orientations were the same as those stated above for compact BC aggregates (cases GIS and GI), but were slightly higher for lacy BC aggregates: $1.1 \pm 0.0$ for case FIS and $2.0 \pm 0.1$ for case FI. This illustrated the significance of using
a sufficient number of target orientations to converge on predicted optical properties using DDSCAT.

The compactness of the BC aggregate influenced the MAC of BC-NaCl mixtures. Higher MAC amplification factors are found for internally mixed compact BC (with even less coating amounts) than for internally mixed lacy BC. Compared to bare BC, the MAC of the mixtures increased because (i) BC is surrounded by NaCl, which has a larger refractive index than the surrounding bulk medium (air) (Bohren, 1986; Flanner et al., 2012) and (ii) light is internally reflected in the non-absorbing NaCl (Fuller et al., 1999). Additionally, radiation is focused near the center of the particle, enabling further absorption enhancement from inclusions that happen to reside near the center of the mixture. Bohren (1986) and Adachi et al. (2010) also discuss the effect of the position of BC in a host material.

In the 550 to 1000 nm region, the AAE for coated particles increases as BC becomes increasingly embedded in NaCl. In the region between 200 and 550 nm, AAE decreases when the embedding of BC in NaCl increases (see Table 2). As with bare BC, the AAE of BC internally mixed with NaCl is smaller in the 200 to 550 nm range than in the 550 to 1000 nm range.

Predicted values of SSA are shown in Fig. 7b. The mixing of BC with NaCl amplifies both absorption and scattering, but scattering increases more than absorption and, therefore, SSA increases. For the cases studied, SSA tends to decrease at wavelengths below 400 nm. This feature is a characteristic of the size of this aerosol mixture, and it is also a feature
The phase function describes how much light is scattered in each direction. The refractive index of BC and NaCl has been considered constant in the spectral range between 200 and 1000 nm, where \( n_{BC} = 1.95 - 0.79i \) and \( n_{NaCl} = 1.5 \) and the density of BC \((\rho_{BC})\) is 1.8 g cm\(^{-3}\). All the computed optical values are averaged over 1000 particle orientations and satisfy the condition \( |m|kd < 0.3 \). The spectral resolution is 100 nm.

**3.3 Scattering phase function and polarization**

Scattering phase functions at 466 and 733 nm for bare and coated BC are presented in Fig. 8. The phase function describes how much light is scattered in each direction. The peak of the scattering phase function is connected to the size of the particle, where an increase in particle size leads to an increase in forward scattering. As shown in Fig. 8, the phase function also depends on aggregate compactness and mixing state. The phase function of lacy BC (case F) has a narrower peak of the scattering phase function is connected to the size of the particle, where an increase in particle size leads to an increase in forward scattering. At 466 and 773 nm, forward scattering increases when BC is totally embedded in NaCl (compare case F with FI and case G with GI). This effect is much less pronounced when BC is only partially embedded (compare case F with FIS and case G with GIS). At 466 nm, increasing the mixing of BC with NaCl reduces the phase function in the backscattering direction (compare case F with FI and FIS and case G with GI and GIS). At 733 nm, scattering phase functions are similar (despite the difference in size) for bare BC and BC particles that are not fully embedded in NaCl (cases F and FIS and cases G and GIS), and a marked reduction in backscatter is evident only when BC is completely embedded in NaCl (cases FI and GI).

The degree of linear polarization, \(-S_{12}(\theta)/S_{11}(\theta)\), is shown in Fig. 9. Perfectly polarized radiation has a degree of linear polarization equal to 1, whereas unpolarized radiation has a degree of linear polarization equal to 0. At 466 and
733 nm, the particles with $a_{\text{eff}}$ between 82 and 130 nm exhibit bell shape curves (Rayleigh regime), whereas larger particles closer to the radiation wavelength present multiple modes including a negative degree of polarization at different angles. This complex structure is characteristic of Mie scattering and due to interferences of partial waves originating from different spatial regions inside the particle (i.e., different scattering angles) (Tyynelä et al., 2007). The negative sign of degree of linear polarization indicates that the scattered light is polarized parallel to the reference plane, whereas a positive degree of polarization indicates that the light is polarized perpendicular to the reference plane. At 773 nm, negative polarization features are evident only for the lacy BC completely embedded in NaCl (case FI with $a_{\text{eff}} = 303$ nm), where $-S_{12}(\theta)/S_{11}(\theta)$ shows a negative degree of polarization between 80 and 120 degrees. The case GI presents a bell shaped curve with a peak at 120 instead of 90 degrees. At shorter wavelengths, when the size of the particle and wavelengths are more comparable, $-S_{12}(\theta)/S_{11}(\theta)$ shows more complicated features (resonances) than at 773 nm, with a negative degree of polarization starting at smaller angles (i.e., for the case FI).

4 Summary and discussion

In this study, models of bare BC and BC internally mixed with NaCl were developed based on SEM and TEM images, and optical properties including MAC, AAE, SSA, scattering phase function, and polarization were predicted over the 200 to 1000 nm range using DDSCAT, which applies the discrete dipole approximation (DDA). DDA is applicable to particles with arbitrary shape and anisotropic composition, which allows computation of optical properties of particles with complex chemistry and morphology, whereas other approaches require unrealistic simplifications such as averaging the refractive indexes of mixed composition particles (like the effective medium theory).

Key results include the following: (i) lacy aggregates have a higher MAC and lower SSA than compact aggregates, which is consistent with other modeling studies. (ii) Computed MAC are consistent with measured values of $7.5 \pm 1.2 \text{ m}^2 \text{ g}^{-1}$. The amplification factors of MAC attributed to the mixing of BC with NaCl vary from 1.0 to 2.4 depending on the position of the BC aggregate in the NaCl and the compactness of the BC aggregate. Higher amplification factors are found for compact aggregates completely embedded in NaCl. (iii) The variation in absorption with wavelength does not adhere precisely to a power law relationship over the 200 to 1000 nm range. Consequently, the AAE depends on the wavelength range over which it is computed. The AAE of bare BC aggregates is sensitive to the level of compactness and monomer size, with smaller values for compact rather than lacy aggregates. (iv) SSA values are strongly sensitive to the particle shape approximation and porosity. Further, computed values of SSA at 550 nm range between 0.16 and 0.27 for lacy and compact aggregates, respectively, in agreement with reported experimental values of $0.25 \pm 0.05$. The SSA of BC internally mixed with NaCl (100–300 nm in radius) is higher than for bare BC and increases with embedding in NaCl. The SSA (of internally mixed BC) decreases in the 200–400 nm wavelength range, a feature also typical of the optical properties of dust and organics. (v) The linear polarization of scattered sunlight is strongly dependent on particle size and shape. Bare BC (with a radius of 80 nm) presents in the linear polarization a bell shape feature, which is a characteristic of the Rayleigh regime. When BC is internally mixed with NaCl (100 and 300 nm in radius), the linear polarization presents complex features characteristic of Mie scattering.

In radiative transfer calculations that are used to interpret space or ground-based observations, various assumptions are made regarding the aerosol optical properties. It is common
to approximate aerosol shape as homogeneous spherical or spheroidal particles, ignoring the effect of realistic morphology and mixing with other aerosol compounds. The results of this study indicate that there are significant differences in the optical properties of BC when modeled as an aggregate compared to the equivalent volume sphere (HSA), and in the optical properties of bare BC and internally mixed BC. Therefore, assuming spherical instead of irregularly shaped particles in radiative transfer calculations can lead to significant errors in retrieved parameters, such as the aerosol type, optical thickness, particle size distributions, and composition (see Dlugach and Petrova, 2003 for a complete discussion of errors). Similarly, the SSA of BC coated with NaCl exhibits features that are common to the optical properties of dust and organics, which could be misleading when inferring aerosol composition from measurements of SSA. Lastly, since Jacobson (2000) and others have demonstrated that BC mixing state strongly influences radiative forcing, deriving optical properties that are consistent with the complex morphology and mixing state of aerosols is warranted. The DDA model employed in this study, which has not yet been widely applied in climate assessments, may prove useful in addition to other more widely used models.

Acknowledgements. The authors are grateful to Jeffrey Cuzzi, Patrick Hamill, Bob Bergstrom and Diane Wooden for the valuable scientific discussion, and further to Luca Scarnato for suggesting reference-standard algorithms and graphical tools for image processing. We thank Jeffery Aguiar for providing the TEM images in Fig. 4 and Anthony Strawa for providing the access to the SEM at NASA Ames. The authors thank the referees for providing constructive comments and help in improving the contents of this paper.

The source of the DDSCAT code is available at the website http://www.astro.princeton.edu/~draine/.

This research was supported by an appointment to the NASA Postdoctoral Program at Ames Research Center, administered by Oak Ridge Associated Universities through a contract with NASA, and by the Radiation Sciences Program in the Earth Science Division of the Science Mission Directorate, National Aeronautical and Space Administration via award NNH09AK98I.
